ABSTRACT

We show that the mass fraction of GMC gas ($n \gtrsim 100 \text{ cm}^{-3}$) in dense ($n \gg 10^4 \text{ cm}^{-3}$) star-forming clumps, observable in dense molecular tracers ($L_{\text{HCN}}/L_{\text{CO}(1-0)}$), is a sensitive probe of the strength and mechanism(s) of stellar feedback. Using high-resolution galaxy-scale simulations with pc-scale resolution and explicit models for feedback from radiation pressure, photoionization heating, stellar winds, and supernovae (SNe), we make predictions for the dense molecular gas tracers as a function of GMC and galaxy properties and the efficiency of stellar feedback. In models with weak/no feedback, much of the mass in GMCs collapses into dense sub-units, predicting $L_{\text{HCN}}/L_{\text{CO}(1-0)}$ ratios order-of-magnitude larger than observed. By contrast, models with feedback properties taken directly from stellar evolution calculations predict dense gas tracers in good agreement with observations. Changing the strength or timing of SNe tends to move systems along, rather than off, the $L_{\text{HCN}} - L_{\text{CO}}$ relation (because SNe heat lower-density material, not the high-density gas). Changing the strength of radiation pressure (which acts efficiently in the highest density gas), however, has a much stronger effect on L_{HCN} than on L_{CO} . We predict that the fraction of dense gas ($L_{\text{HCN}}/L_{\text{CO}(1-0)}$) increases with increasing GMC surface density; this drives a trend in $L_{\text{HCN}}/L_{\text{CO}(1-0)}$ with SFR and luminosity which has tentatively been observed. Our results make specific predictions for enhancements in the dense gas tracers in unusually dense environments such as ULIRGs and galactic nuclei (including the galactic center).

Key words: star formation: general — galaxies: formation — galaxies: evolution — galaxies: active — cosmology: theory

1 INTRODUCTION

Feedback from massive stars is critical to the evolution of galaxies, the properties and structure of the ISM, and the formation of stars and star clusters in giant molecular clouds. The Kennicutt-Schmidt law for star formation in galaxies implies a gas consumption time of ~ 50 dynamical times (Kennicutt 1998). Moreover, the total fraction of the gas turned into stars in GMCs over their lifetime is only a few percent (Zuckerman & Evans 1974; Williams & McKee 1997; Evans 1999; Evans et al. 2009).

In an instantaneous sense, the low star formation rate in GMCs is closely related to the fact that most of the gas within GMCs is at relatively low densities $n \sim 10 - 100 \text{ cm}^{-3}$, i.e., *not* in star-forming cores that have densities $\gtrsim 10^4 \text{ cm}^{-3}$ (e.g. Williams & McKee 1997; Evans 1999, and references therein). Tracers of high-density gas such as the HCN transition (critical density $n \gtrsim 10^4 \text{ cm}^{-3}$) have shown that it is the gas at these high densities that is actually forming stars – what determines the SFR in GMCs is the amount of mass at these densities (e.g. Shirley et al. 2003; Wu et al. 2005; Lada et al. 2010). In typical GMCs, this is $\sim 10\%$ of the mass, but star formation is relatively rapid in the clumps, giving the canonical SFR of a few percent of the GMC mass per dynamical time.

Furthermore, observations have suggested that in high-density systems such as local merger-induced starbursts – which are known to have a higher ratio of SFR to gas surface densities $\Sigma_{\text{sfr}}/\Sigma_{\text{gas}}$ (Kennicutt 1998) – have systematically higher ratios of high-density to total gas mass (Gao & Solomon 2004b; Narayanan et al.

2005; Evans et al. 2006; Bussmann et al. 2008; Wu et al. 2010). The systematic increase of this ratio with surface density Σ_{gas} has been proposed as the origin of the difference between the apparently linear SFR-dense gas mass relation (which follows if the mass at a specific high-density has a high, constant star formation efficiency) and the super-linear Kennicutt-Schmidt relation (Gao & Solomon 2004b; Wu et al. 2005; Krumholz & Thompson 2007, but see also Yao et al. 2003; Narayanan et al. 2008b,a).

Exactly what determines the amount of dense gas, and hence the SFR, remains unknown. In simulations without stellar feedback, GMCs experience runaway collapse to densities much higher than observed, and rapidly turn a near-unity fraction of their gas into stars (Hopkins et al. 2011a; Tasker 2011; Bounaud et al. 2010; Dobbs et al. 2011; Krumholz et al. 2011; Harper-Clark & Murray 2011). Neither thermal pressure nor turbulence in and of itself can stave off collapse in the ISM: cooling is rapid, so that thermal support is quickly lost, and turbulent support dissipates on a single crossing time (e.g., Ostriker et al. 2001). Some mechanism must therefore continuously inject energy and momentum into the gas on both GMC and galactic scales, in order to prevent runaway collapse to arbitrarily high densities.

Various physical mechanisms have been proposed as a source of random motions in GMCs: photo-ionization, stellar winds, radiation pressure from UV and IR photons, proto-stellar jets, cosmic rays, supernovae, and gravitational cascades from large scales (e.g. Mac Low & Klessen 2004, and references therein). In Hopkins et al. (2011a) (hereafter Paper I) and Hopkins et al. (2012) (Paper II), we therefore developed a library of numerical hydrodynamic simulations of galaxies, with pc-scale resolution, molecular

* E-mail: phopkins@astro.berkeley.edu

cooling, and explicit spacial/time resolution of feedback mechanisms including radiation pressure in the UV and IR, supernovae, massive and AGB stellar winds, and HII photo-ionization heating. In Paper I and Paper II, we show that these feedback mechanisms generically lead to the formation of a self-regulating, quasi steady-state multiphase ISM, in which dense GMCs form via gravitational collapse. Gas inside these GMCs then forms parsec scale clumps at densities $n > 10^4 \text{ cm}^{-3}$ in which most stars form; the GMCs hosting these clumps are then quickly broken up by feedback after they turn a few percent of their mass into stars.

We showed in Paper II that most properties of the ISM and GMCs are insensitive to the strength and precise mechanisms of feedback, so long as *sufficient* feedback is present to resist runaway dissipation and collapse. But this is largely a property of the low-density (non-star forming) gas in GMCs – their properties are set to be those of any marginally self-gravitating object, i.e. they trace the Jeans mass and collapse conditions (Hopkins 2011). The gas at high densities can, in principle, evolve very far away from its “initial” conditions even in just a couple GMC dynamical times. In this paper, we investigate the consequences of different feedback mechanisms for the dense gas in galaxies and GMCs.

2 THE SIMULATIONS

The simulations used here are described in detail in Paper I (Sec. 2 & Tables 1-3) and Paper II (Sec. 2). We briefly summarize the most important properties here. The simulations were performed with the parallel TreeSPH code GADGET-3 (Springel 2005). They include stars, dark matter, and gas, with cooling, star formation, and stellar feedback.

Gas follows an atomic cooling curve with additional fine-structure cooling to $< 100 \text{ K}$, with no “cooling floor” imposed. Star formation is allowed only in dense regions above $n > 1000 \text{ cm}^{-3}$, at a rate $\dot{\rho}_* = \epsilon \rho_{\text{mol}} / t_{\text{ff}}$ where t_{ff} is the free-fall time, $\rho_{\text{mol}} = f_{\text{H}_2} \rho$ is the molecular gas density, and $\epsilon = 1.5\%$ is a nominal efficiency at these densities (Krumholz & Tan 2007). We follow Krumholz & Gnedin (2011) to calculate the molecular fraction f_{H_2} in dense gas as a function of local column density and metallicity. In Paper I and Paper II we show that the galaxy structure and SFR are basically independent of the small-scale SF law (independent of ϵ in particular), density threshold (provided it is high), and treatment of molecular chemistry.

Stellar feedback is included, via a variety of mechanisms.

(1) **Local Momentum Flux** from Radiation Pressure, Supernovae, & Stellar Winds: Gas within a GMC (identified with an on-the-fly friends-of-friends algorithm) receives a direct momentum flux from the stars in that cluster/clump. The momentum flux is $\dot{P} = \dot{P}_{\text{SNe}} + \dot{P}_w + \dot{P}_{\text{rad}}$, where the separate terms represent the direct momentum flux of SNe ejecta, stellar winds, and radiation pressure. The first two are directly tabulated for a single stellar population as a function of age and metallicity Z and the flux is directed away from the stellar center. Because the local momentum flux is, by definition in our simulations, interior to clouds, the systems are always optically thick to ultraviolet radiation, so the radiation force is approximately $\dot{P}_{\text{rad}} \approx (1 + \tau_{\text{IR}}) L_{\text{incident}} / c$, where $1 + \tau_{\text{IR}} = 1 + \Sigma_{\text{gas}} \kappa_{\text{IR}}$ accounts for the absorption of the initial UV/optical flux and multiple scatterings of the IR flux if the region is optically thick in the IR (with Σ_{gas} calculated for each particle given its location in the GMC).

(2) **Supernova Shock-Heating:** Gas shocked by supernovae can be heated to high temperatures. We tabulate the SNe Type-I and Type-II rates from Mannucci et al. (2006) and STARBURST99,

respectively, as a function of age and metallicity for all star particles and stochastically determine at each timestep if a SNe occurs. If so, the appropriate mechanical luminosity is injected as thermal energy in the gas within a smoothing length (nearest 32 gas neighbors) of the star particle. Given typical smoothing lengths, the Sedov-Taylor phase is resolved.

(3) Gas Recycling and Shock-Heating in Stellar Winds:

Gas mass is returned to the ISM from stellar evolution, at a rate tabulated from SNe and stellar mass loss (integrated fraction ≈ 0.3). The SNe heating is described above. Similarly, stellar winds are assumed to shock locally and inject the appropriate tabulated mechanical luminosity $L(t, Z)$ as a function of age and metallicity into the gas within a smoothing length.

(4) **Photo-Heating of HII Regions:** We also tabulate the rate of production of ionizing photons for each star particle; moving radially outwards from the star, we then ionize each neutral gas particle (using its density and state to determine the necessary photon number) until the photon budget is exhausted. Ionized gas is maintained at a minimum $\sim 10^4 \text{ K}$ until it falls outside an HII region.

(5) **Long-Range Radiation Pressure:** Photons which escape the local GMC (not accounted for in mechanism (1) above) can be absorbed at larger radii. Knowing the intrinsic SED of each star particle, we attenuate integrating the local gas density and gradients to convergence. The resulting “escaped” SED gives a flux that propagates to large distances, and can be treated in the same manner as the gravity tree to give the local net incident flux on a gas particle. The local absorption is then calculated integrating over a frequency-dependent opacity that scales with metallicity, and the radiation pressure force is imparted.

In implementing (1)-(5), all energy, mass, and momentum-injection rates are taken from stellar population models (Leitherer et al. 1999), assuming a Kroupa (2002) IMF, without any free parameters. More details, numerical tests, and resolution studies (up to 10^9 particles with sub-pc softening lengths) for these models are discussed in Paper II.

We implement the model in four distinct initial disk models spanning a range of galaxy types. Each has a bulge, stellar and gaseous disk, halo, and central BH (although to isolate the role of stellar feedback, models for BH growth and feedback are disabled). At our standard resolution, each model has $\sim 0.3 - 1 \times 10^8$ total particles, giving particle masses of $500 - 1000 M_\odot$ and $1 - 5 \text{ pc}$ smoothing lengths, and are run for a few orbital times each. A couple ultra-high resolution runs for convergence tests employ $\sim 10^9$ particles with sub-pc resolution. The disk models include:

(1) SMC: an SMC-like dwarf, with baryonic mass $M_{\text{bar}} = 8.9 \times 10^8 M_\odot$ (gas $m_g = 7.5 \times 10^8 M_\odot$, bulge $M_b = 1.3 \times 10^8 M_\odot$, the remainder in a stellar disk m_d) and halo mass $M_{\text{halo}} = 2 \times 10^{10} M_\odot$. The gas (stellar) scale length is $h_g = 2.1 \text{ kpc}$ ($h_d = 0.7$).

(2) MW: a MW-like galaxy, with halo $M_{\text{halo}} = 1.6 \times 10^{12}$, and baryonic $(M_{\text{bar}}, m_b, m_d, m_g) = (7.1, 1.5, 4.7, 0.9) \times 10^{10} M_\odot$ with scale-lengths $(h_d, h_g) = (3.0, 6.0) \text{ kpc}$.

(3) Sbc: a gas-rich dwarf starburst disk with halo $M_{\text{halo}} = 1.5 \times 10^{11}$, and baryonic $(M_{\text{bar}}, m_b, m_d, m_g) = (10.5, 1.0, 4.0, 5.5) \times 10^9 M_\odot$ with scale-lengths $(h_d, h_g) = (1.3, 2.6) \text{ kpc}$.

(4) HiZ: a high-redshift massive starburst disk (typical of intermediate SMGs at $z \sim 2 - 4$); $M_{\text{halo}} = 1.4 \times 10^{12} M_\odot$ (scaled for $z = 2$ halos), and baryonic $(M_{\text{bar}}, m_b, m_d, m_g) = (10.7, 0.7, 3, 7) \times 10^{10} M_\odot$ with scale-lengths $(h_d, h_g) = (1.6, 3.2) \text{ kpc}$.

Figure 1. Distribution of “cold” ($T < 1000$ K) gas densities n in each of the different disk galaxy models, with different feedback mechanisms (§ 2) enabled. “Standard” means all mechanisms are included. In the “no feedback” case, gas piles up at $n \gg 10^4 \text{ cm}^{-3}$. Even though SNe can regulate the *global* galaxy properties, including just thermal feedback mechanisms (SNe & stellar wind shock-heating and HII photo-ionization) without radiation pressure or momentum flux (“no momentum flux”) leads to a similar excess at high- n . Removing the heating mechanisms while keeping the radiation pressure (“rad mom only”) has a modest effect on the high- n gas, even though it can dramatically change the galaxy wind and thermal state. If we make feedback stronger by simply increasing the strength of the radiation pressure momentum flux by a factor of 30, the amount of high- n material is strongly suppressed. Remarkably, these changes have almost no effect on the median densities of cold gas ($n \sim 10 - 100 \text{ cm}^{-3}$) – i.e. typical densities of gas in GMCs – or the corresponding GMC mass function & linewidths (nor do they much alter the galaxy gas velocity dispersion or disk scale height; see Paper II). It is the dense gas that traces the effects of feedback.

3 HIGH-DENSITY GAS & FEEDBACK

In Figure 1, we plot the distribution of cold gas ($T < 1000$ K, mostly in GMCs) densities in each simulation. We show this for models with various feedback mechanisms enabled or disabled in turn. The basic properties of the “standard” model (all feedback enabled) are discussed in Paper II: the distribution has a lognormal core (dispersion $\sim 1 - 1.5$ dex) with median $\langle n \rangle \sim 100 \text{ cm}^{-3}$, in good agreement with observations. As discussed in § 1, the behavior of this “core” is not very sensitive to the model – they are just set by the conditions for gravitational collapse in a turbulent ($Q \sim 1$) disk (see Hopkins 2011). The *average* GMC properties (sizes, linewidths, densities, etc) are not sensitive tracers of feedback.

But the high- n tail shows significant differences between models. Turning off feedback entirely leads to runaway collapse with a large secondary peak at $n \rightarrow 10^6 \text{ cm}^{-3}$ (the maximum resolved density). Turning off “heating” mechanisms (shock-heating by SNe and stellar winds and photo-ionization heating) leads to a small increase in the amount of high-density $n \gtrsim 10^4 \text{ cm}^{-3}$ material in the MW and SMC models. But in all models, even the MW and SMC cases – where we show in Paper II that SNe heating may dominate the *global* self-regulation of the disk and generation of galactic winds (Hopkins et al. 2011b) – turning off radiation pressure (while still keeping SNe, stellar wind, and photo-heating) yields a much more dramatic increase in the amount of very dense material. In the HiZ and Sbc models, this is nearly as significant as turning off all feedback. In other words, even where global self-regulation

can be set by SNe heating, the dense material at $n \gtrsim 10^4 \text{ cm}^{-3}$ is regulated by radiation pressure. This should be expected: at these densities optical depths are large in the infrared, and cooling times for SNe remnants are $\sim 10^4$ times shorter than the dynamical time.

We illustrate how this very dense gas can function as a tracer of the strength of radiation pressure by also comparing a series of otherwise identical models where we simply multiply the local radiation pressure force applied by a large, constant factor $\eta_p = 30$ everywhere in the simulation. Again, the median $\langle n \rangle$ is similar in both cases. However, to maintain global equilibrium, the boosted-feedback model requires much lower star formation rates (and mass in young stars). In turn, the high- n tail (where stars actually form) is much smaller.

4 COMPARISON WITH OBSERVATIONS

In Figure 2, we consider what these differences mean in terms of observational tracers. The total mass budget in intermediate-density molecular gas, roughly gas with $n \gtrsim 100 \text{ cm}^{-3}$, is commonly traced by the CO(1-0) transition. Since we know the mass in gas above this density, we can use the observed relation $M_{\text{mol}} \approx 4.8 L_{\text{CO}(1-0)} / (\text{K km s}^{-1} \text{ pc}^2)$ (Young & Scoville 1991) to estimate L_{CO} . Similarly, the HCN luminosity L_{HCN} is related to the mass above its critical density, $n_{\text{crit}} \approx 6 \times 10^4 \text{ cm}^{-3}$, as $M(n > n_{\text{crit}}) \approx 5.5 L_{\text{HCN}} / (\text{K km s}^{-1} \text{ pc}^2)$ (Gao & Solomon 2004a). Another high-density tracer is CO(3-2), with $n_{\text{crit}} \approx 1.5 \times 10^4 \text{ cm}^{-3}$ and $M(n > n_{\text{crit}}) \approx 1.33 L_{\text{CO}(3-2)} / (\text{K km s}^{-1} \text{ pc}^2)$ (Narayanan et al. 2005). All of these conversions are uncertain at the factor of ~ 2 level, but a more accurate prediction would require a full non-LTE radiative transfer solution (outside the scope of this paper), and in any case, such a systematic offset does not change our conclusions. For example, we contrast the results with the choice of the surface-density and metallicity-dependent α_{CO} derived in Narayanan et al. (2011), and obtain similar results.

Because we cannot follow gas to arbitrarily high densities where star formation actually occurs, the simulations enforce the observed relation between dense gas mass and star formation efficiency (and indeed most of the star formation occurs in gas with resolved densities $\gtrsim 10^4 \text{ cm}^{-3}$). This means they automatically reproduce the observed $L_{\text{HCN}} - \text{SFR}$ or $L_{\text{HCN}} - L_{\text{IR}}$ relations: they define our star formation prescription.¹

However, Figure 1 shows that the relative amount of high-density ($n \gtrsim 10^4 \text{ cm}^{-3}$) and intermediate-density/total molecular ($n \gtrsim 100 \text{ cm}^{-3}$) gas can vary dramatically. The relevant diagnostic is therefore the mass fraction in GMCs that is in dense cores, $M_{\text{dense}}/M_{\text{tot}}$, traced in $L_{\text{HCN}}/L_{\text{CO}(1-0)}$ or $L_{\text{CO}(3-2)}/L_{\text{CO}(1-0)}$. Figure 2 plots this as a function of total cold gas mass $L_{\text{CO}(1-0)}$. For both tracers, we compare the observed relations:

$$\frac{L_{\text{HCN}}}{L_{\text{CO}(1-0)}} \propto 0.1 \left(\frac{L_{\text{CO}(1-0)}}{10^{10} \text{ K km s}^{-1} \text{ pc}^2} \right)^{0.4} \quad (1)$$

$$\frac{L_{\text{CO}(3-2)}}{L_{\text{CO}(1-0)}} \propto 0.1 \left(\frac{L_{\text{CO}(1-0)}}{10^{10} \text{ K km s}^{-1} \text{ pc}^2} \right)^{0.5} \quad (2)$$

(Gao & Solomon 2004a; Narayanan et al. 2005).

¹ If we arbitrarily raise/lower the efficiency of star formation in the dense gas, we will systematically shift the amount of dense gas required for the SFR and corresponding feedback strength needed to self-regulate while preserving otherwise similar galaxy properties (this is shown explicitly in Figure 8 of Paper I). Hence this would also alter the density PDFs and $L_{\text{HCN}} - L_{\text{CO}}$ relations in Figures 1-2, but at the expense of manifestly violating the observed $L_{\text{HCN}} - \text{SFR}$ and $L_{\text{HCN}} - L_{\text{IR}}$ relations.

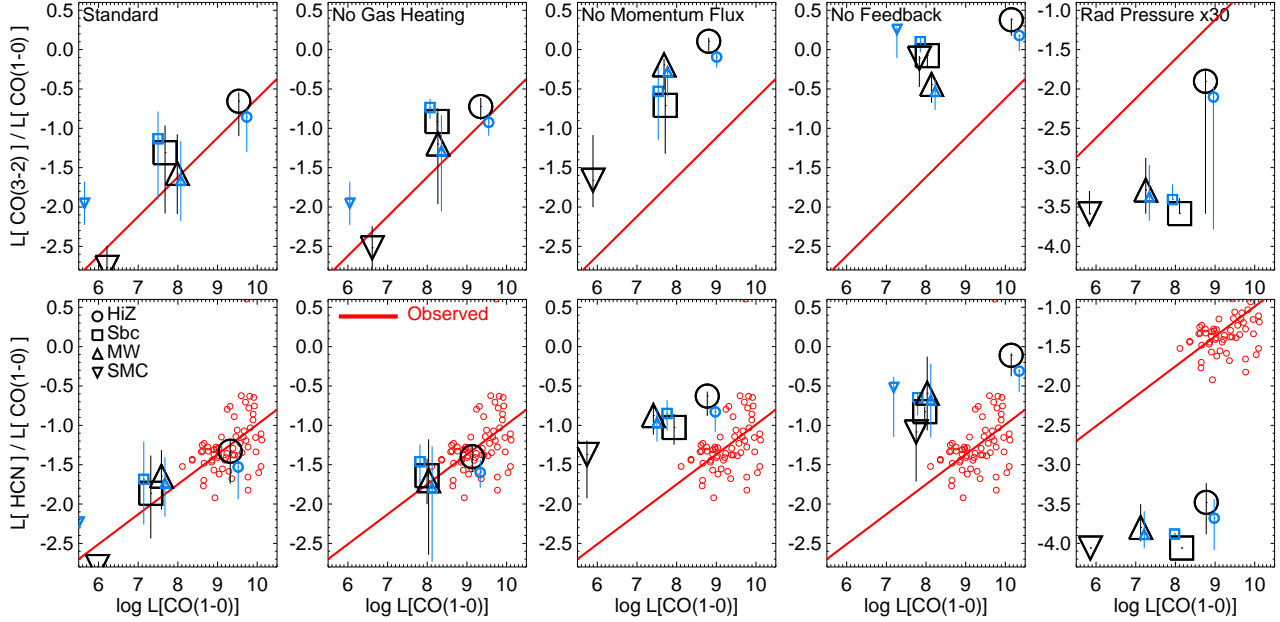

Figure 2. Dependence of observational dense-gas tracers on feedback and galaxy properties. We show the predicted ratio of the luminosity in HCN(1-0) (bottom) and CO(3-2) (top), with critical densities $n_{\text{crit}} \sim 6 \times 10^4, 1.5 \times 10^4 \text{ cm}^{-3}$, to the luminosity in CO(1-0), which traces the total molecular/GMC mass ($n \gtrsim 100 \text{ cm}^{-3}$). This is a proxy for the ratio of very dense star-forming gas, to total GMC mass, as a function of gas mass/SFR. The median and scatter in time for each galaxy model is plotted (points with error bars). Large black points adopt a constant α_{CO} , small blue points adopt $\alpha_{\text{CO}}(\Sigma_{\text{H}_2}, Z)$ from Narayanan et al. (2011). The observed best-fit trend (line) and data points (small circles) are taken from Gao & Solomon (2004a). We compare models with different feedback mechanisms, as Fig. 1: our standard model; no gas heating from SNe, stellar winds, or photo-heating; no radiation pressure momentum flux; no feedback; and radiation pressure boosted by 30. While global average GMC properties are similar in these models, the ratio of very dense to GMC gas mass, and hence the relative luminosity in tracers like HCN, are sensitive to feedback. Gas heating has little effect on HCN because cooling times are so short at these densities, but adjusting the strength of radiation pressure leads to a nearly linear scaling in the predicted HCN luminosities. In our standard models, the predictions agree well with observations, both in the typical magnitude $L_{\text{HCN}}/L_{\text{CO(1-0)}}$ (a consequence of “normal” feedback strength), and the trend with $L_{\text{CO(1-0)}}$, which stems from rising surface densities in more luminous systems.

In the “standard” (all feedback enabled) models, the predicted ratios of dense-to-cold gas and the scaling with gas mass/luminosity/SFR agree remarkably well with observations.

5 WHAT DETERMINES DENSE CORE FRACTIONS & HCN LUMINOSITIES?

How does this scaling arise in our simulations? Dense clumps form and collapse until they produce sufficient stars such that the local feedback can offset gravity and disrupt the clump (generate a force $F_{\text{feedback}} \sim GM_{\text{cl}}^2/R^2 \sim GM_{\text{cl}}\Sigma_{\text{cl}}$). The total force needed to unbind the GMC is then $F_{\text{tot}} \sim GM_{\text{GMC}}\Sigma_{\text{GMC}}$. If all the feedback acting on the GMC is from young stars currently in dense clumps (and coupled therein), then the total force is simply the sum over the forces acting in each dense region i , $F_{\text{tot}} = \sum F_{\text{dense},i} = G \sum M_{\text{dense},i} \Sigma_{\text{dense},i} = GM_{\text{dense,tot}} \langle \Sigma_{\text{dense}} \rangle$. Equating the two gives $M_{\text{dense}}/M_{\text{GMC}} \sim \Sigma_{\text{GMC}}/\langle \Sigma_{\text{dense}} \rangle$.

More generally, the stars form in dense regions, but these can have a lifetime which is short compared to the massive stellar evolution timescale ($\sim 5 \text{ Myr}$). For clumps that live for $N_t \sim 1$ free-fall times, the fraction of the GMC luminosity in dense clumps is $f_L \approx 0.1 n_4^{-1/2} N_t$, where $n_4 \equiv \langle n_{\text{cl}} \rangle / 10^4 \text{ cm}^{-3}$. As Figure 1 shows, the dense gas is most affected by the local radiation pressure. The total force (momentum deposition rate) from radiation pressure in a (smooth) clump with average optical depth τ in the IR is $\dot{p} = (1 + \tau)L/c$; the total \dot{p} in the GMC is then $(1 + [\tau_{\text{dense}} - \tau_0]f_L + \tau_0)L/c$ (where L is the total stellar luminosity, $\tau_0 = \kappa \Sigma_{\text{GMC}}$ is the mean τ of the GMC as a whole, and $\tau_{\text{dense}} = \kappa \Sigma_{\text{dense}}$ is the mean τ of a dense

clump). We can estimate the required $L_{\text{cl}}/M_{\text{cl}}$ for each dense clump by again equating the force to gravity, and then $L = f_L^{-1} \sum L_{\text{cl}}$. Using this and equating the total force on the GMC to its self-gravity (and assuming $\tau_{\text{dense}} \gtrsim 1 \gg \tau_0$), we obtain

$$\frac{M_{\text{dense}}}{M_{\text{GMC}}} \approx \frac{f_L \tau_0}{1 + f_L \tau_{\text{dense}} + \tau_0} \quad (3)$$

$$\approx \frac{0.03 N_{t,3} n_4^{-1/2} \Sigma_{\text{GMC},100}}{1 + 0.3 N_{t,3} n_4^{-1/2} \Sigma_{\text{dense},1000} + 0.1 \Sigma_{\text{GMC},100}} \quad (4)$$

$$\rightarrow \frac{\Sigma_{\text{GMC}}}{\Sigma_{\text{dense}}} (n_4^{-1/2} \Sigma_{\text{dense},1000} \gg 1) \quad (5)$$

where $N_{t,3} = N_t/3$, $\Sigma_{\text{GMC},100} \equiv \Sigma_{\text{GMC}}/100 M_{\odot} \text{ pc}^{-2}$ (~ 1 for typical GMCs, i.e., in non-ULIRGs), $\Sigma_{\text{dense},1000} \equiv \Sigma_{\text{dense}}/1000 M_{\odot} \text{ pc}^{-2}$ (~ 1 for typical dense clumps), and $n_4 \equiv n_{\text{dense}}/10^4 \text{ cm}^{-3}$. In simulations, we find typical $N_t \approx 2-4$; if we assume a fixed SFR per free-fall time $\dot{M}_* = \epsilon M_{\text{dense}}/t_{\text{free-fall,dense}}$ and use the above derivation to obtain the critical L/M in a dense clump, we predict $N_t \approx 3(0.05/\epsilon)$. These values agree well with observational estimates (Evans et al. 2009, and references therein). Note that one might expect a dependence on metallicity, since the opacities τ appear; however, accounting for it properly (assuming opacity scales linearly with metallicity), the dependence on metallicity cancels nearly completely.

The predicted ratio $M_{\text{dense}}/M_{\text{GMC}}$ increases with Σ_{GMC} . We saw in Paper II that Σ_{GMC} increases with average galaxy surface density (hence galaxy SFR and luminosity). This drives the

trend of increasing $L_{\text{HCN}}/L_{\text{CO}(1-0)}$ at higher luminosities in Figure 2. Observationally, from the baryonic Tully-Fisher relation ($R_g \propto M_g^{0.25-0.33}$) (e.g. Stark et al. 2009), we expect (for Jeans-scale clouds) average surface densities $\Sigma_{\text{GMC}} \propto M_g^{0.3-0.5}$ (which fits well the direct estimates in Paper II). This leads to the prediction that $L_{\text{HCN}}/L_{\text{CO}(1-0)} \propto L_{\text{CO}(1-0)}^{(0.3-0.5)}$ for “normal” galaxies (with an upper limit when $M_{\text{dense}}/M_{\text{GMC}} \sim 1$). Similar considerations can be used to derive the observed IR-CO(1-0) scaling (Andrews & Thompson 2010).

Note that this argument assumes that Σ_{dense} *does not* increase with average galaxy surface density, or at least not as rapidly as Σ_{GMC} does. There is some observational evidence that, at the highest clump masses, Σ_{dense} does not increase with increasing clump mass (e.g. Figure 8 in Murray 2009).

This simple force argument also predicts, for example, that in local LIRGs and ULIRGs, where enhanced star formation is driven by extremely dense nuclear concentrations of gas, and so Σ_{GMC} *must* be large (it must be at least the mean density), the dense gas fraction or $L_{\text{HCN}}/L_{\text{CO}(1-0)}$ will be systematically larger. This has been observed (Gao & Solomon 2004b; Narayanan et al. 2005; Evans et al. 2006; Bussmann et al. 2008). Moreover, we can estimate the magnitude of this enhancement: in typical ULIRG nuclei, where the effect will be most extreme, the surface densities reach $\Sigma \gtrsim 10^3 M_{\odot} \text{pc}^{-2}$, reaching the limit where $L_{\text{HCN}}/L_{\text{CO}(1-0)} \sim M_{\text{dense}}/M_{\text{GMC}} \sim \langle \Sigma \rangle / \Sigma_{\text{dense}} \sim 0.1 - 1$ (i.e. where the dense gas fractions saturate) a factor ~ 10 larger than that in normal galaxies. This agrees well with the enhancements in L_{HCN} observed for ULIRGs and dense relative to normal spiral galaxies in Gao & Solomon (2004b); Juneau et al. (2009).

6 DENSE TRACERS VERSUS FEEDBACK

Based on the derivations above, we can guess how the HCN and CO luminosities will behave under various changes to the feedback model, shown in Figure 2. Because it has little effect on the most dense gas, removing gas heating has a weak effect on the predicted correlations, even in the MW and SMC models. Note that it can move systems *along* the correlations – it does so by globally regulating the mass in winds, and so the total mass forming GMCs and ultimately forming stars (e.g. absolute $L_{\text{CO}(1-0)}$). But within GMCs, heating has little effect, since the cooling time is so short. Removing the local direct radiation pressure momentum flux, however, has a much more dramatic effect, similar to removing all forms of feedback entirely. In both cases, there is little or nothing to resist runaway collapse inside the GMCs, and dense gas piles up until it saturates at fractions of order unity relative to the total GMC mass (Figure 1). These produce order-of-magnitude or larger discrepancies with the observations (in the SMC and MW case, momentum flux from SNe resist complete collapse, but the amount of dense gas is still ~ 10 times too large for the observations). On the other hand, if we artificially boost the local radiation pressure strength by a large factor, the dense gas is all removed. If we repeat the derivations above, with the radiation pressure force multiplied uniformly by a factor η , the predicted $M_{\text{dense}}/M_{\text{GMC}}$ in the non-saturated regime ($\Sigma_{\text{GMC}} \ll \Sigma_{\text{dense}}$) simply scales $\propto \eta^{-1}$. This is what we find – the predicted $L_{\text{HCN}}/L_{\text{CO}(1-0)}$ decreases approximately linearly in proportion to the “boost” in feedback strength.

7 DISCUSSION

We have used a library of numerical hydrodynamic simulations of galaxies, with pc-scale resolution, molecular cooling, and explicit

spatial/time resolution of feedback mechanisms including radiation pressure in the UV and IR, supernovae, massive and AGB stellar winds, and HII photo-ionization heating to study how the properties of dense gas – i.e. the gas where stars actually form – can be a sensitive tracer of the effects of feedback and a strong constraint on models of star formation and stellar feedback. In Paper I and Paper II, we show that these feedback mechanisms generically lead to the formation of a self-regulating, quasi steady-state multiphase ISM, in which dense GMCs form via gravitational collapse. The GMCs then form clumps at densities $n > 10^4 \text{cm}^{-3}$ in which most stars form. These stars, which have a total mass amounting to only a few percent of the GMC mass, then disrupt their parent GMCs. We showed in Paper II, however, that *most* properties of the ISM and GMCs are insensitive to the feedback mechanism or strength of feedback, so long as some mechanisms are present that are sufficient to resist runaway dissipation and collapse in these GMCs. Considering models with e.g. the dominant feedback mechanism being radiation pressure, SNe, HII photo-heating, or stellar winds; or models with different density thresholds, power-law dependencies, or efficiencies of star formation in dense sub-clumps; or models where we arbitrarily multiply/divide the strength of feedback by large factors; we find that provided something can make GMCs short-lived, their global properties (mass functions, densities, size-mass and linewidth-size relations, virial parameters, and ISM velocity dispersions, scale-heights, phase structure, and Toomre Q parameters) largely reflect global gravitational conditions rather than e.g. some local hydrostatic equilibrium that would be sensitive to the details of star formation and/or feedback on small scales.

However, we show here that the properties of the very dense gas, $n \gtrsim 10^4 \text{cm}^{-3}$, *are* sensitive to the strength and nature of feedback. If feedback is inefficient, then dense regions within GMCs will collapse and accrete until a large fraction of the GMC mass is in dense clumps. If, on the other hand, feedback is efficient, then only a small fraction of the dense clumps within a cloud collapse before sufficient massive stars are formed to unbind the parent cloud. The ratio of mass in dense gas – traced by dense molecular transitions such as L_{HCN} – to the total mass of cool gas – traced by lower-density transitions such as $L_{\text{CO}(1-0)}$ – is therefore a sensitive measure of feedback efficiencies. In models with weak or no feedback, we show that the predicted ratio $L_{\text{HCN}}/L_{\text{CO}(1-0)}$ is an order-of-magnitude or more larger than observed. In models with feedback efficiencies taken “as is” from stellar evolution models, the predicted ratio agrees well with that observed. But if we arbitrarily make feedback more or less strong, multiplying the momentum flux by some factor η , then the predicted $L_{\text{HCN}}/L_{\text{CO}(1-0)}$ ratio scales approximately as η^{-1} ; a model with 30 times stronger radiation pressure predicts ~ 30 times lower $L_{\text{HCN}}/L_{\text{CO}(1-0)}$.

The predicted ratios are sensitive not just to the absolute strength of feedback, but also to the mechanisms of feedback. The thermal energy deposited by SNe explosions, for example, can have dramatic effects on galaxy scales (puffing up galaxy disks, driving turbulence, and accelerating material into galactic super-winds), once it escapes from dense gas to efficiently heat low-density material. But it has almost no effect directly *within* the high-density gas, because the post-shock cooling time at these densities is $\sim 10^4$ times shorter than the dynamical time. We therefore predict that this mechanism has little effect on the observed $L_{\text{HCN}}-L_{\text{CO}(1-0)}$ relation, except to move galaxies *along* the relation by globally regulating the amount of (previously low-density) gas which can cool into new GMCs. Radiation pressure, on the other hand, can provide a very strong source of feedback at these densities, because these regions can be optically thick. Direct observations of massive star-

forming regions have begun to suggest such a scenario (Lopez et al. 2011); correlating this with observations of the dense-to-low density gas mass ratio would provide a mechanism-specific diagnostic of feedback strength.

In addition to the normalization (median ratio $L_{\text{HCN}}/L_{\text{CO}}$), we show also that the systematic trends in $L_{\text{HCN}} - L_{\text{CO}}$ with e.g. SFR, L_{IR} , or L_{CO} are tracers of feedback properties. We predict that the ratio of dense to total gas increases with increasing SFR and luminosity, in a manner in good agreement with observations. This arises because higher-SFR systems tend to have higher cloud surface densities (equivalently, higher pressures) and therefore require more force (more star formation, for the same feedback efficiencies) to unbind. We therefore predict a correlation between the dense gas ratio tracers and cloud surface densities of the form $\propto \Sigma_{\text{GMC}}$ (at low surface densities; it must saturate at higher densities), which should explain some of the observed scatter in nominal cloud lifetimes, dense gas formation efficiencies, and star formation efficiencies. This specifically predicts an enhanced ratio of $L_{\text{HCN}}/L_{\text{CO}(1-0)}$ in extreme systems such as ULIRGs and galaxy nuclei, and very high-redshift starburst disks – these systems have disk-average surface densities Σ in excess of the “typical” MW Σ_{GMC} , so must have significantly higher Σ_{GMC} . This should also manifest in even higher-density tracers such as HCN(3-2) (see e.g. Bussmann et al. 2008), for which our models here predict a more dramatic difference in the most extreme systems (but begins to push against our resolution limits). Such an enhancement has been tentatively observed; we provide a motivation for further observations to constrain how this scales with GMC and galaxy properties, as a means to directly constrain the efficiency of feedback as a function of these parameters.
